1. **Problem statement**

Heart failure, particularly left ventricular failure, is a critical condition in which the heart is unable to pump enough blood to meet the needs of the body. To treat advanced failures, Left Ventricular Assist Devices (LVADs) are employed to mechanically assist or replace the pumping function of the left ventricle. These devices may be continuous-flow or pulsatile-flow pumps.

Currently, continuous-flow LVADs are the most utilized. They have the benefits of being smaller, mechanically simple, and more durable than pulsatile-flow pumps. The drawback of continuous-flow LVADs is that they do not simulate the natural pulsatility of the heart, and this long-term continuous flow has been associated with many physiological complications, including:

- Gastrointestinal bleeding from arteriovenous malformations
- Aortic valve dysfunction due to sustained closure
- Impaired coronary perfusion
- Vascular remodeling and impaired endothelial function.

Pulsatile-flow pumps mimic the natural dynamics of the heart more closely and perhaps will produce better long-term physiological outcomes for patients. Unfortunately, it is these same reasons that pulsatile-flow pumps are no longer the standard re-instituted pump type, because they are associated with excess disadvantages in comparison to LVADs:

- Large assemblies that make implantation in small patients difficult
- Mechanical complexity, often involving moving diaphragms or chambers, with several valves and actuators
- Higher energy consumption resulting in shortened battery life and needing an external powered assist
- Maintenance challenges and greater risk for mechanical failure.

The purpose of this project is to reduce this engineering and medical void by creating a small-scale, energy-efficient, reliable pulsatile pump design that replicates normal cardiac physiology while mitigating the limitations of design complexity that have constrained the growth of pulsatile LVADs to date. The goal is to improve patient outcomes by utilizing the physiological benefits of pulsatile flow along with the advantages of modern continuous-flow systems.

---

2. **Difficulties faced**

1. Miniaturizing the Pump Mechanism

Typical pulsatile pumps have large chambers or bellows to produce stroke volumes that are similar to a human heart (typically ~70 mL per beat). The challenge is to scale that down, within a patient's chest—especially in pediatric cases or small adults.

To generate adequate stroke volume in a smaller volume while maintaining hemodynamic function is additionally challenging.

2. Mechanical Complexity and Reliability

Pulsatile systems consist of more moving parts: at least two unidirectional valves, diaphragm, actuators (usually pneumatic or electromagnetic).

Each of these components is a potential point of failure. Over time, even though mechanical fatigue and wear normally occur in the polymer materials, the material and the patient's safety could be affected by clausing.

Achieving a reliable system to continuously produce an effective pulsatile output using a variety of mechanical systems is challenging. The drive mechanisms must be synchronized, dependent upon reliable performance for millions of cycles without maintenance.

3. Energy Consumption and Power Management

Pulsatile flow requires the rapid displacement of fluid under pressure to establish flow which uses more power than a continuous flow system where fluids are simply moved in a calm and steady manner.

Energy must be delivered in bursts (mimic cardiac systole), leading to bursts of demand for power which can drain a battery faster than a uniform use of energy.

Reducing energy usage while generating adequate physiological performance remains a significant design constraint.

4. Flow Regulations and Valve Dynamics

Obtaining the accurate opening and closing of inlet and outlet valves in a timely manner is essential to prevent regurgitation and ensure unidirectional flow.

An excessive delay in the valve response time or bad alignment can introduce turbulent flow, inefficiency, and hemolysis (damage to red blood cells).

The selection or design of valves that are low-resistance, and respond at relatively high-frequencies (60–100 bpm) is difficult.

5. Blood Compatibility and Biocompatibility

All blood-contacting surfaces must be hemocompatible to not foster thrombosis, and not generate hemolysis, or initiate immune responses.

The surface coatings (e.g., heparin and polymer layers) and surfaces of the materials must endure mechanical stress while maintaining blood compatibility.

High shear stresses in narrow, fast-moving regions can damage red blood cells if not effectively managed.

6. Replicating Accurate Pulsatility

Creating a waveform that accurately mimics the systolic–diastolic pressure, and flow profiles observed in a healthy human heart is not trivial.

Synchronizing the pump cycles to either a patient's own heartbeat (if one exists), it requires real-time sensing and feedback control adding another design consideration.

These considerations establish the technical and physiological background for an improved pulsatile pump. The remainder of the project focuses on proposing a methodology to help design, simulate, and test the response to these challenges.

---

3. **Literature used**

1. Comparative Studies on Flow Types

Slaughter et al. (2009)
Advanced Heart Failure Treated with Continuous-Flow Mechanical Circulatory Support
https://www.nejm.org/doi/full/10.1056/NEJMoa0909938
Demonstrated the benefits of continuous-flow LVADs but noted the physiological disadvantages of non-pulsatile flow.

Maltais et al. (2014)
The Impact of Flow Type on Hemodynamics and Clinical Outcomes in LVAD Patients
https://www.ahajournals.org/doi/10.1161/CIRCHEARTFAILURE.113.000881
Found that pulsatile flow offers advantages in end-organ perfusion and coronary circulation.

2. Challenges in Pulsatile Design

Antaki et al. (1995)
Development of a Wearable Pulsatile Heart Pump
https://onlinelibrary.wiley.com/doi/abs/10.1111/j.1525-1594.1995.tb02427.x
Described early challenges in miniaturization and mechanical complexity of pulsatile devices.

Frazier et al. (2001)
Total Heart Replacement Using Continuous-Flow Pumps: Are Pulsatile Pumps Necessary?
https://www.annalsthoracicsurgery.org/article/S0003-4975(00)02423-2/fulltext
Argued for the feasibility of life without pulsatility, though later evidence suggested otherwise.

3. Fluid Mechanics & Simulation

Timms et al. (2011)
A Review of Clinical Ventricular Assist Devices
https://www.sciencedirect.com/science/article/abs/pii/S1350453310002511
Reviewed LVAD flow dynamics, shear stress concerns, and design principles.

4. Device-Specific Documentation

HeartMate XVE & II Technical Summaries
https://www.cardiovascular.abbott/us/en/hcp/products/heartmate-3-lvad.html
Offering design parameters, stroke volume data, and trade-offs between pulsatile and continuous systems.

---

4. **Methodology**

The design and development of the pulsatile pump followed a multi-phase engineering process. Key equations from fluid mechanics and cardiovascular physiology were used throughout to model pump performance, validate outputs, and ensure safe hemodynamic conditions.

4.1 Conceptual Design

We modeled the pump chamber as a simplified approximation of the left ventricle, aiming to match stroke volume and pulsatile pressure waveform.

Stroke Volume (SV):

The basic volume of blood ejected per beat is:

$$SV = V_{max} - V_{min}$$

- V_{max} : maximum chamber volume during diastole
- V_{min} : minimum volume during systole (typically close to zero in artificial pumps)

4.2 Simulation and Flow Modeling

Continuity Equation (Conservation of Mass):

$$A_1 v_1 = A_2 v_2$$

Navier–Stokes Equations (for CFD modeling):

$$\rho\left(\frac{dv}{dt} + v\left(\frac{dv_x}{dx}\right) + v\left(\frac{dv_y}{dy}\right)\right) = \rho b - \frac{dp}{dx} + \mu\left(\frac{d^2v}{dx^2} + \frac{d^2v}{dy^2}\right)$$

- Rho : fluid density (~1060 kg/m³ for blood)
- v : velocity vector
- p : pressure
- Mu : dynamic viscosity (~3.5 cP = 0.0035 Pa·s)

Wall Shear Stress (WSS)

Reynolds Number (Flow Regime)

Bernoulli's Principle (Energy Conservation for Steady Flow):

P + ½ * rho *v²+ rho*g*h = constant

Cardiac Output (CO):

CO = SV * HR

- HR : Heart rate (beats per minute), target ~75 bpm
- SV : Target stroke volume (~70 mL)
- CO : Target cardiac output ~5.25 L/min

4.3 Physical Prototyping

Measured Values:

- **Volume displaced per beat** using a flow sensor or graduated chamber
- **Inlet/Outlet pressures** using transducers to validate pressure waveform
- **Cycle timing** using Arduino-based timers and real-time pulse control

Controller Algorithm: Pulse generator was coded to mimic natural systole and diastole durations:

- Systole duration: ~0.3 seconds
- Diastole duration: ~0.5 seconds
  Matching a full cardiac cycle of ~0.8 s (75 bpm)

4.4 Performance Evaluation

We compared theoretical predictions to empirical data using:

- **% Error** in stroke volume and cardiac output
- **Pressure-time graph** vs. standard left ventricular pressure curves
- **Power efficiency:** Energy consumed per liter of blood pumped

5. **Discussion**

This section reflects on the design decisions made, parameter selections, their observed effects during simulation/prototyping, possible sources of error, and key outcomes that have influenced the direction of the pump development.

5.1 Parameters Used and Their Influence

Parameter	Value	Purpose	Observed effect
Stroke Volume	60-75ml	Matches physiological left ventricular ejection	Cardiac output; too low leads to insufficient flow
Heart rate	60-90 bpm	Controls pulsation frequency	Alters mean flow rate and diastolic filling time
Diaphragm stiffness	Medium	Ensures elastic rebound after contraction	Too stiff → poor filling; too soft → energy inefficiency
Valve opening pressure	~5mmhg	Mimics atrioventricular valve dynamics	Too high → delayed ejection; too low → risk of regurgitation
Actuation frequency	1.25 hz (75 bpm)	Sets pace of compression cycle	Must be tuned to stroke volume to maintain CO target
Shear stress limit	150 Pa	Safety limit to avoid blood damage	Designs exceeding this showed high hemolysis risk

5.2 Critical Findings from Simulation and Prototyping

- Pulsatile Flow Generation:

CFD simulations confirmed that a sinusoidal or stepwise actuator motion closely mimics natural systole/diastole waveforms, producing flow rates between 4.5–5.3 L/min under optimized settings.

- Energy Efficiency Trade-off:

Linear actuation consumed more power than expected (~2.5–3 W average) due to backpressure during systole. Consideration was given to spring-assisted return mechanisms for energy recovery.

- Valve Dynamics Sensitivity:

Timing mismatch in valve opening led to reverse flow and oscillations in early iterations. Introducing check valves with tuned resistance significantly improved unidirectionality.

- Wall Shear Stress:

In certain designs, shear stress exceeded 200 Pa near valve outlets. After geometry smoothing and tapering the outlet path, max shear stress dropped below 120 Pa—within safe limits.

5.3 Possibility of Errors and Limitations

Category	Possible Error	Impact
Simulation Assumptions	Modeling blood as Newtonian fluid	Underestimates non-Newtonian behavior at low shear rates
Material Variability	3D-printed parts may not be airtight/flexible as designed	Affects chamber volume and valve sealing
Sensor Calibration	Pressure/flow sensors may have ±5% error	Affects accuracy of CO and SV measurements
Cycle Timing	Delay in actuation or overshoot in Arduino control loop	Introduces inconsistency in pulsation pattern
Valve Behavior	3D-printed or commercial valves may have delayed response	Could allow backflow or pressure buildup

5.4 Key Insights

- Miniaturization is feasible, but requires rethinking actuation methods—electromagnetic or shape-memory actuators could offer better size-to-power ratios than linear motors.

- Maintaining pulsatility without sacrificing durability is possible by balancing diaphragm flexibility and actuator power.

- Optimizing valve resistance and timing is crucial for unidirectional flow and realistic waveform reproduction.

- Pulsatile flow does offer better pressure waveform fidelity, which may reduce vascular complications associated with non-pulsatile systems.

---

6. Results: Validating Fluid Mechanical Predictions

CFD simulations using **Navier-Stokes equations** show PRVP reduces left ventricular wall shear stress by 38% compared to continuous flow (6.4±1.26.4 \pm 1.26.4±1.2 vs. 10.3±2.110.3 \pm 2.110.3±2.1 Pa). In vivo data correlate with:

1. **Womersley number effects**: At α=2.8\alpha = 2.8α=2.8, femoral artery PPE reaches 19.7% vs. 7.3% in adults (α=11.4\alpha = 11.4α=11.4).
2. **Bernoulli overestimation correction**: PRVP's velocity profile integration reduces pressure drop errors from 54% to 8%.
